

Proportional Hazards Regression tree analysis of training sample of 1,002 cases to model survival outcomes on dependent variables - death_5yr. The analysis resulted in a simple tree with only two terminal nodes, identifying X17p_status as the primary split variable. According to the analysis, if the status of X17p is "Loss," the case is assigned to Node 2 with a higher relative hazard coefficient of 1.174; otherwise, it falls into Node 3 with a lower coefficient of -0.133. X17p_status was ranked as the most significant variable at the root node, followed by X8p_status.
